Evaluation of Municipal Stormwater-Monitoring Network, Dallas-Fort Worth, Texas, 1992–2000

By Timothy H. Raines, Susan C. Gándara, and David S. Brown

Abstract

About 450 stormwater samples were collected from the municipal stormwater-monitoring network, Dallas-Fort Worth area, during February 1992–June 2000. Two-hundred ten samples were collected from a 30-site network of predominantly single-land-use sites during 1992–1994, and each sample was analyzed for 188 properties and constituents. Two-hundred thirty-eight samples were collected from a 22-site network during 1997–2000, and each sample was analyzed for 23 properties and constituents.

The current 22-site network was evaluated on the basis of land use, water quality, hydraulic, and rainfall characteristics. Land-use data for 1990 and 1995 was aggregated into seven categories. The seven cities in the area typically are about 35-percent residential, 10-percent commercial, 5-percent industrial, 5-percent highway, 35-percent undeveloped, and 10-percent water and other. The 22-site network consists of 4 residential, 4 commercial, 4 industrial, 3 highway, 1 undeveloped, and 6 mixed land-use sites. Statistically significant differences in concentrations of diazinon and oil and grease between 1992–94 samples and 1997–2000 samples were most common among constituents. Four sites have hydraulic problems affecting the accuracy and representativeness of sample collection. Because of the annual distribution of storms, more frequent sampling during February–September than during March–August is reasonable.

Three network alternatives were developed on the basis of the current network evaluation. All three alternatives propose collecting three samples per year at each current or reactivated site (two samples from September–February and one sample during March–August) and six samples per year at each new site (three samples from September–February and three samples during March–August). The first alternative consists of discontinuing two sites and adding one new site. The second alternative consists of discontinuing four sites and adding one new site. The third alternative consists of discontinuing 7 sites, reactivating 1 site, and adding 3 sites.

INTRODUCTION

During 1992–94, the U.S. Geological Survey (USGS), in cooperation with the North Central Texas Council of Governments (NCTCOG), collected samples to characterize stormwater runoff from predominantly single-land-use sites for the seven cities and two Texas Department of Transportation (TxDOT) Districts in the Dallas-Fort Worth (DFW) area. These data were used by the cities and TxDOT in the application process for National Pollutant Discharge Elimination System (NPDES) stormwater permits. Cities with populations of 100,000 or greater and TxDOT districts with population centers of 100,000 or greater are required to obtain permits from the U.S. Environmental Protection Agency (EPA) to discharge stormwater into the Nation's waters (U.S. Environmental Protection Agency, 1990). The following cities and districts in the DFW area met the population criteria: Arlington, Dallas, Fort Worth, Garland, Irving, Mesquite, Plano, TxDOT Dallas District, and TxDOT Fort Worth District.

The stormwater discharge permits issued to the seven cities and two TxDOT districts in 1997 required additional sampling for a 5-year period. In 1997, the USGS began a study in cooperation with the NCTCOG to collect stormwater samples and characterize stormwater runoff for the seven cities and two TxDOT districts for the period 1997–2001. In 2000, the USGS began a study in cooperation with the NCTCOG to evaluate the existing stormwater-monitoring network and propose possible changes to the network design and sampling schedule.

Purpose and Scope

This report presents the evaluation of the existing stormwater-monitoring network and proposes alternatives for future data collection. The analysis was limited to 105 samples collected at 15 sites during 1992–94 and 238 samples collected at 22 sites (15 original sites and 7 new sites) during February 1997–September 2000. Selected statistical tests were used in the analysis. The land uses for the sites and for the cities were compared.

Description of the Study Area

The DFW area is located in north-central Texas (fig. 1) and lies within Collin, Dallas, Denton, and Tarrant Counties. Of the seven cities, three (Arlington, Dallas, and Fort Worth) have populations greater than 250,000 (North Central Texas Council of Governments, 1993). The DFW area is in the upper Trinity River Basin with three major tributaries of the Trinity River draining the 1,700-square-mile area—West Fork Trinity River, Elm Fork Trinity River, and East Fork Trinity River. Mean annual precipitation in the study area varies from about 31 inches in Tarrant County to 36 inches in Dallas County, with the months of April and May typically the wettest and the months of July and August the driest (Ramos, 1999).

Monitoring Network

Thirty monitoring sites were established during 1992–93 in small (160 acres or less) drainage basins, each categorized by a single predominant land use (11 residential, 9 industrial, 6 commercial, and 4 highway). Five sites each were located in the cities of Dallas and Fort Worth, four in Arlington, three each in Garland, Irving, Mesquite, and Plano, and two sites each in TxDOT Dallas and TxDOT Fort Worth. Fifteen of the original 30 monitoring sites (1–15, table 1) were reactivated for the 1997–2000 sampling period, including 4 residential, 4 industrial, 4 commercial, and 3 highway. Three sites each are located in Dallas and Fort Worth, two sites each in Arlington and TxDOT Dallas, and one site each in Garland, Irving, Mesquite, Plano, and TxDOT Fort Worth. The remaining 15 original sites were discontinued for the 1997–2001 sampling period (16–30, table 1). Seven

new sites (31–37, table 1) were established during 1997–98. One site is located in each of the seven cities; no new TxDOT sites were established. Six of the new sites are located in drainage basins with mixed land use, and one site is located in an undeveloped drainage basin. Three of the six sites with mixed land use are located at outfalls with drainage areas less than 500 acres, and the remaining three sites are located instream with drainage areas of at least 2,500 acres (table 1). Most of the monitoring sites are located at storm-sewer outfalls or in concrete-lined open channels. Two sites are located at natural channels.

Sample Collection and Analysis

Two conditions are required for sample collection: (1) Antecedent dry-weather conditions (no more than 0.1 inch of precipitation in a 24-hour period) during the 72 hours before the storm event to allow for accumulation of possible contaminants, and (2) the total storm precipitation should range from 0.2 to 1.5 inches (Baldys and others, 1998).

During 1992–94, seven samples were collected at each of the 30 sites and analyzed for 188 selected properties and constituents (Baldys and others, 1997). During the 1997–2001 sampling period, the 13 samples scheduled for the 15 reactivated sites and the 24 samples scheduled for the 7 new sites will be analyzed for a reduced list of 23 properties and constituents. The sampling schedule is divided into two 6-month periods (September–February and March–August), during which a predetermined number of samples are to be collected. For the reactivated sites, five samples were scheduled in the first year (two samples in the first 6-month period and three samples in the next period) and two samples per year (one in each 6-month period) for the following 4 years. For the new sites, six samples per year (three in each 6-month period) are scheduled for the last 4 years of the 5-year period. Table 1 lists the number of samples scheduled for the 1997–2001 period and the number of samples actually collected during February 1997–August 2000. Some samples were not collected as scheduled because of extended periods of little or no precipitation, backwater conditions, or equipment failure.

Two types of samples are collected for analysis of water-quality properties and constituents. Grab samples are collected manually, and composite samples are collected by an automatic sampler. The samples are analyzed

for selected properties and constituents in accordance with guidelines set by EPA (U.S. Environmental Protection Agency, 1992). Figure 2 shows an example of the accumulated precipitation, the discharge, and the times of the grab and composite aliquot samples for a storm sampled on May 15, 1997, at site 08056390 Bastille Street Outfall at La Reunion Parkway, Dallas.

A grab sample typically is collected during the first 2 hours of a storm to catch the first flush of the basin—the initial stormwater runoff that often contains accumulations of possible contaminants. Grab samples are analyzed for fecal coliform bacteria, fecal streptococcus bacteria, oil and grease, phenols (TxDOT Dallas only), and field properties. The field properties—specific conductance, pH, and water temperature—are measured at the time of sample collection.

A composite sample is a combination of discharge-weighted sample aliquots collected throughout a storm by the automatic sampler programmed to collect discrete samples after a site-specific, specified volume of flow has passed the site. Composite samples are analyzed for biochemical oxygen demand, chemical oxygen demand, suspended solids, dissolved solids, ammonia plus organic nitrogen, nitrite plus nitrate nitrogen, total phosphorus, dissolved phosphorus, arsenic, cadmium, chromium, copper, lead, nickel (TxDOT Dallas only), zinc, and diazinon.

Acknowledgments

Keith Kennedy and Larry Nierth NCTCOG, provided the land-use, cities, and drainage-basin geographic information system (GIS) coverages used in this report. Jennifer Lanning-Rush, USGS, provided GIS assistance and Jennifer Pribyl, Stanley Baldys III, Ernest Baker, Mike Dorsey, Dana Barbie, Phil Soenksen, Mary Jane Turner, and Ben Dietsch, USGS, reviewed the hydrologic and water-quality data.

EVALUATION OF MONITORING NETWORK

The current (2001) 22-site network was analyzed on the basis of available land-use data, measured water-quality data, hydraulic site characteristics, and rainfall characteristics.

Land-Use Characteristics

Land-use data from 1990 and 1995 (figs. 3, 4), the drainage basins for 19 of the 22 sites, and the jurisdictional boundaries of the seven cities in the DFW area were provided by the NCTCOG. The land-use data were aggregated into the following major categories: residential, commercial, industrial, highway, undeveloped, water, and other. The land-use subcategories of single family, multi-family, mobile home parks, and group quarters were classified as residential. The land-use subcategories of office, retail, institution, and hotel and motel were classified as commercial. The land-use subcategories of transportation, roadway, and airport were classified as highway. The land-use subcategories of utilities, parks and recreation, flood control, under construction, and parking were classified as other. The land-use categories of industrial, undeveloped, and water consisted only of those single land uses. The land use summarized by category for the 22 active sites and seven cities are listed in table 2.

Of the 16 predominantly single-land-use sites (excludes mixed), the site land-use characterization matches the land use in at least 70 percent of the upstream basin area for all except Pylon Street Outfall (Fort Worth) (table 2). The majority of the drainage basin for Pylon Street Outfall, classified as an industrial outfall, is

undeveloped. The majority of the drainage basin for the Mountain Creek Outfall site (TxDOT) consists of highway median draining a large hillside. Although the Beck Branch (Plano) undeveloped site drains a basin predominantly zoned as industrial, the only existing development includes the roads and associated drainage and one building constructed since the site was established. The Sycamore Creek (Fort Worth) and Rush Creek (Arlington) mixed-land-use sites primarily are a mix of residential and undeveloped land. The smaller mixed-land-use sites Mills Branch (Garland) and Knights Branch (Dallas) are about 50-percent residential, and the Cottonwood Branch site (Irving) is about 50-percent industrial. Drainage-basin data for the North Mesquite Creek site were not available from NCTCOG.

Land use associated with the 15 predominately single-land-use sites did not change substantially from 1990 to 1995. For the large mixed-land-use sites, the amount of undeveloped land decreased slightly and the amount of residential, commercial, and industrial land use increased slightly between 1990 and 1995. There was a decrease in residential land and an increase in undeveloped land associated with the Eastern Hill High School Outfall (Fort Worth) for unknown reasons. The Beck Branch Outfall site reflects a decrease in industrial land use and an increase in highway land use between 1990 and 1995, which reflects the construction of new roads in the drainage basin.

The current (2001) 22-site network drains only about 6.6 percent of the area of the seven cities. Without the Sycamore Creek, Rush Creek, and North Mesquite Creek (Mesquite) sites, the remaining 19 sites would represent about 0.3 percent of the area of the seven cities. The cities typically are about 35-percent residential, 10-percent commercial, 5-percent industrial, 5-percent highway, 35-percent undeveloped, and 10-percent water and other.

Water-Quality Characteristics

Of the 238 samples that were collected during February 1997–August 2000, 107 samples were analyzed at the USGS National Water Quality Laboratory (NWQL) in Denver, Colo., and the remaining samples were analyzed at the Armstrong Laboratory in Arlington, Tex. The Armstrong Laboratory currently (2001) is involved in the process of being certified as a USGS-approved laboratory.

Summary statistics were computed for 23 properties and constituents included in the 1997–2000 sampling. Statistical tests were applied to a subset of the properties and constituents to test for differences between sites within the same land-use group. Twenty-four samples were not used in the analysis because the composite samples were not deemed representative of the entire storm event.

Selection of Constituents

Of the 23 properties and constituents analyzed during 1997–2000, 10 were selected for the additional analysis. Two constituents from grab samples were analyzed (fecal coliform and oil and grease), and eight constituents from composite samples were analyzed (nitrite plus nitrate, biochemical oxygen demand, chemical oxygen demand, suspended solids, dissolved solids, copper, lead, and diazinon). The samples were selected on the basis of being representative of major groups, NWQL approval of that constituent at the Armstrong Laboratory, and the number of concentrations measured above the detection levels.

Summary Statistics

Logarithmic plotting distribution estimation techniques (Helsel and Cohn, 1988) were used to compute statistics for constituent concentrations less than the laboratory minimum reporting level (MRL). The logarithmic plotting distribution estimation technique also can be used for constituents with multiple MRLs (Helsel and Cohn, 1988) such as diazinon. The use of the robust probability-plot method has been shown to perform well for estimating summary statistics and reducing errors that would be introduced using other methods (Helsel and Hirsch, 1992).

Simple boxplots (figs. 5–14) are used to display the period-of-record data for each site for the 10 constituents selected for this analysis because they provide a concise graphical summary of the distributions of the data. Boxplots show center of the data (median), variation of spread (interquartile range), skewness (quartile skew), and presence or absence of unusual values. A simple boxplot is constructed by ranking data from smallest to largest, and a box is drawn from the 25th to the 75th percentile. The box length is from the 25th percentile to the 75th percentile. The box length equals the interquartile range. A line is drawn through the box at the median. “Whiskers” are then drawn from the quartiles to the maximum and minimum data values.

Summary statistics for each of the 15 original sites were computed for all of the analyzed constituents for the 1992–94 period and the 1997–2000 period and for the seven new sites for the 1997–2000 period as shown in table 3. Summary statistics also were computed for each of the 10 major constituents discussed in this report for each land use for the two sampling periods of the project as shown in table 4. Apparent differences by land use for each of the 10 major constituents are discussed below.

The median concentrations of nitrite plus nitrate for the six land-use categories for data from both periods ranged from 0.42 to 0.73 milligrams per liter (mg/L). The median concentration for the highway land-use sites increased from 0.6 mg/L for the 1992–94 period to 0.73 mg/L for the 1997–2000 period. The median concentration for the new mixed land-use sites was 0.6 mg/L and for the undeveloped land-use site was 0.65 mg/L for the 1997–2000 period.

The median concentrations of biochemical oxygen demand for the six land-use categories for data from both periods ranged from 6.3 to 8.3 mg/L. The median concentration for the commercial land-use sites increased from 4.95 mg/L for the 1992–94 period to 7.30 mg/L for the 1997–2000 period. The median concentration for the new mixed land-use sites was 8.3 mg/L and for the undeveloped land-use site was 4.2 mg/L for the 1997–2000 period.

The median concentrations of chemical oxygen demand for the six land-use categories for data from both periods ranged from 5.0 to 69.5 mg/L. The median concentration for the 1997–2000 period was less than that of the 1992–94 period for the four land-use groups. The median concentration for the residential land-use sites

decreased from 69.5 to 59.5 mg/L. The median concentration for the commercial land-use sites decreased from 47.0 to 38.0 mg/L. The median concentration for the industrial land-use sites decreased from 61.0 to 32.8 mg/L. The median concentration for the highway land-use sites decreased from 59.0 to 44 mg/L. The median concentration for the new mixed land-use sites was 36.7 mg/L and for the undeveloped land-use site was 5.0 mg/L for the 1997–2000 period.

The median concentrations of suspended solids for the six land-use categories for data from both periods ranged from 28.0 to 278.0 mg/L. The median concentration for the commercial land-use sites increased from 28.0 mg/L for the 1992–94 period to 42.0 mg/L for the 1997–2000 period. The median concentration for the highway land-use sites increased from 88 mg/L for the 1992–94 period to 134 mg/L for the 1997–2000 period. The median concentration for the new mixed land-use sites was 278.0 mg/L and for the undeveloped land-use site was 200.5 mg/L for the 1997–2000 period.

The median concentrations of dissolved solids for the six land-use categories for data from both periods ranged from 50.0 to 209.5 mg/L. The median concentration for the residential land-use sites increased from 60.0 mg/L for the 1993–94 period to 76.0 mg/L for the 1997–2000 period. The median concentration for the new mixed land-use sites was 148.0 mg/L and for the undeveloped land-use site was 118.5 mg/L for the 1997–2000 period.

The median concentrations of fecal coliform for the six land-use categories for data from both periods ranged from 9,350 to 46,000 mg/L. The median concentration for the commercial land-use sites increased from 9,350 mg/L for the 1992–94 period to 21,500 mg/L for the 1997–2000 period, and the median concentration for the industrial land-use sites increased from 10,000 mg/L for the 1992–94 period to 24,000 mg/L for the 1997–2000 period. The median concentration for the new mixed land-use sites was 46,000 mg/L and for the undeveloped land-use site was 42,000 mg/L for the 1997–2000 period.

The median concentrations of copper for the six land-use categories for data from both periods ranged from 6.0 to 17.0 µg/L. The median concentration for the residential land-use sites increased from 7.0 µg/L for the 1992–94 period to 10.0 µg/L for the 1997–2000 period. For the same periods, the median concentration for the

commercial land-use sites increased from 6.0 µg/L to 9.0 µg/L, and the median concentration for the highway land-use sites decreased from 13.0 µg/L to 10.8 µg/L. The median concentration for the new mixed land-use sites was 17.0 µg/L and for the undeveloped land-use site was 7.50 µg/L for the 1997–2000 period.

The median concentrations of lead for the six land-use categories for data from both periods ranged from 6.2 to 32.0 µg/L. The median concentration for the industrial land-use sites decreased from 32.0 µg/L for the 1992–94 period to 15.2 µg/L for the 1997–2000 period. The median concentration for the new mixed land-use sites was 23.4 µg/L and for the undeveloped land-use site was 6.2 µg/L for the 1997–2000 period.

The median concentrations of diazinon for the six land-use categories for data from both periods ranged from 0.01 to 0.40 µg/L. The median concentration for the residential land-use sites decreased from 0.40 µg/L for the 1992–94 period to 0.18 µg/L for the 1997–2000 period. For the same periods, the median concentration for the commercial land-use sites decreased from 0.10 µg/L to 0.02 µg/L, and the median concentration for the industrial land-use sites decreased from 0.04 µg/L to 0.01 µg/L. The median concentration for the new mixed land-use sites was 0.052 µg/L for the 1997–2000 period; and there were no detections of diazinon for the undeveloped land-use site.

The median concentration of oil and grease for the six land-use categories for data from both periods ranged from 0.2 µg/L to 11.0 µg/L. The median concentration increased for the 1997–2000 period for the four land-use categories with data from both periods. The median concentration for the residential land-use sites increased from 1.0 to 4.0 µg/L. The median concentration for the commercial land-use sites increased from 2.0 to 5.0 µg/L. The median concentration for the industrial land-use sites increased from 0.5 to 3.0 µg/L. The median concentration for the highway land-use sites increased from 0.2 to 3.0 µg/L. The median concentration for the new mixed land-use sites was 3.0 µg/L and for the undeveloped land-use site was 11.0 µg/L for the 1997–2000 period.

Statistical Tests

A Mann-Whitney test (Helsel and Hirsch, 1992) was used to compare the data collected during 1992–94 with the data collected during 1997–2000 at the 15 reactivated sites for a selected property or constituent. The test is a rank-based procedure to determine if the medians for two groups of data are significantly different. A rank-based test is a more robust measure than a parametric test when data are not normally distributed; water-quality data typically are not normally distributed. The null hypothesis is that the medians are the same; the alternative hypothesis is that the medians are different. The null hypothesis is rejected in favor of the alternative hypothesis if the p-value from the test is less than or equal to a predetermined level of significance (alpha level). This test thus indicates whether there were significant temporal changes in the water quality at the 15 sites.

Results of the Mann-Whitney tests (alpha = 0.05) are presented in table 5. Commercial land-use sites consistently indicate that concentrations of diazinon and oil and grease are significantly different between the two sampling periods. Highway sites consistently indicate that concentrations of oil and grease are significantly different between the two periods. Industrial sites consistently indicate that concentrations of chemical oxygen demand and oil and grease are significantly different, and the residential sites consistently indicate that concentrations of suspended solids are significantly different between the two periods.

Results of the Mann-Whitney tests further indicate that oil and grease concentrations generally are higher for all land uses; the reason is unknown. Nitrite plus nitrate, biochemical oxygen demand, dissolved solids, and lead concentrations generally remained unchanged during the two periods for all land uses. Chemical oxygen demand, suspended solids, fecal coliform, copper, diazinon, and oil and grease concentrations showed mixed changes among land uses.

A Kruskal-Wallis test (Helsel and Hirsch, 1992) was used to compare data collected between sites within the same land-use group. The test is a rank-based procedure, similar to the Mann-Whitney test, to determine whether the medians for three or more groups of data are significantly different. The null hypothesis is that the medians are the same; the alternative hypothesis is that the median of at least one group is different. The null hypothesis is rejected in favor of the alternative hypothesis if the p-value from the test is less than or equal to the

alpha level. The Kruskal-Wallis test was used to determine whether there is a significant difference between sites within a land-use group for 10 selected properties and constituents.

Results of the Kruskal-Wallis tests ($\alpha=0.05$) for 10 selected properties and constituents for six land-use groups (table 6) indicate a significant difference at $\alpha=0.05$ between the four residential sites for nitrite plus nitrate, suspended solids, dissolved solids, lead, diazinon, and oil and grease. There is a significant difference between the four commercial sites for chemical oxygen demand, copper, and lead. There is a significant difference between the four industrial sites for nitrite plus nitrate, biochemical oxygen demand, chemical oxygen demand, suspended solids, dissolved solids, copper, and lead. There is a significant difference between the three highway sites for chemical oxygen demand, dissolved solids, fecal coliform, copper, and lead. There is a significant difference between the six mixed sites for nitrite plus nitrate, chemical oxygen demand, suspended solids, dissolved solids, and lead.

A Kruskal-Wallis test also was used to determine if there is a significant difference between land-use groups for the 10 selected properties and constituents (table 7). There is a significant difference between the six land use groups at $\alpha=0.05$ for all 10 properties and constituents.

Hydraulic Characteristics

Hydraulic characteristics for the current (2000) 22-site network were reviewed. Sites that have backwater, confined space, high velocity, or sediment build-up were identified. Sites that have these adverse hydraulic conditions are candidates for removal from the existing network. These hydraulic conditions affect the ability to collect representative flow-weighted samples. Sites with such conditions typically must have rainfall events that are small (0.20–0.50 inch) in order to collect representative flow-weighted samples. Because only small rainfall events can be sampled, the probability of collecting representative stormwater samples is reduced. Backwater conditions occur at sites Bachman Branch Outfall, Dry Branch Outfall, Tributary to Duck Creek

Outfall, and White Rock Creek Outfall; confined space and high velocity conditions exist at site White Rock Creek Outfall; and sediment build-up occurs at Bachman Branch Outfall and Dry Branch Outfall sites.

The larger instream sites (Sycamore Creek, Rush Creek, and North Mesquite Creek) have different hydraulic characteristics than the smaller single-land-use sites. Typically, hydrograph duration is measured in days for instream sites and in hours for single-land-use sites. Real-time flow-weighted compositing is difficult because predicting the volume of runoff for a given storm event is difficult. The predicted runoff volume is used to determine when the sampler will take a sample. Hence, a more appropriate method of sample collection might be to use a timed sampling routine. The samples would be collected on a timed schedule and then individual samples would be flow-weighted after-the-fact. Flow-weighted compositing of the sample would occur after the event in the laboratory.

Rainfall Characteristics

Rainfall characteristics determine when collection of stormwater samples can occur. No rainfall means no stormwater sample. The characteristics of storms for which stormwater samples were collected during the 1992–94 and 1007–2000 are listed in table 8. The distribution of sample collection, by month, is shown below:

Number of stormwater samples collected, by month, 1992–94 and 1997–2000 data combined

	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
Number of samples collected	38	47	66	70	41	26	9	9	27	37	33	54

The fewest and most widely scattered storms during the two sampling periods occurred in June, July, and August. The fewest samples (nine each) were collected in July and August due to dry weather; and the most samples (66 and 70, respectively) were collected in March and April due to wet weather.

Scheduling more frequent stormwater sampling during September–February than during March–August is reasonable. Typically, rainfall in March–August is less frequent and less uniformly distributed than in September–February. If storm sampling is missed for some reason, another opportunity to collect a sample is

more likely occur in the September–February period. Hence, the potential risk for not collecting samples would be minimized if proportionally more samples were scheduled for collection during September–February than March–August.

ALTERNATIVE NETWORK DESIGNS

Possible alternative network designs were developed to guide future data-collection to adequately characterize municipal stormwater runoff in the Dallas-Fort Worth area. Site selection for the development of network alternatives was based on the following five factors: land-use characteristics, water-quality characteristics, hydraulic characteristics, rainfall characteristics, and site location within city boundaries. The current (2000) network consists of 22 sites characterized by upstream basin land use. Two samples per year (one per 6-month period) are scheduled at the 15 reactivated sites, and six samples per year (three per 6-month period) are scheduled at the seven new sites. No further reduction in the number of properties and constituents to be analyzed is proposed.

The first network alternative is summarized in table 9. This alternative consists of discontinuing the two Dallas TxDOT sites and replacing them with one new highway site and collecting three samples per year at each of the 20 current sites in the network and six samples per year at the proposed new site. At each of the current sites, two samples per year would be collected during September–February, and one sample per year would be collected during March–August. A two-to-one ratio for sample collection in September–February and March–August reflects the typical temporal distribution of the number of storms occurring during the two 6-month periods. At the new site, three samples per year would be collected during September–February, and three samples per year would be collected during March–August to be consistent with schedule for the seven sites established in 1997. The Bachman Branch Outfall site is not representative of highway use in the TxDOT Dallas District because it has had a history of a raw-sewage leak, which is reflected in the bacteria data. Also has had backwater and sediment deposition from the downstream catch basin that limits the magnitude of stormwater runoff (less than 0.5 inches) in places where the site can be accurately gaged and sampled. The Mountain Creek

Outfall site also is not representative of highway use in the TxDOT Dallas District because of the large percentage of the drainage area is highway median that drains a hill. Runoff from the hill, which is high in dissolved solids and associated major ions (table 3) does not reflect highway use.

The second network alternative is summarized in table 10. This network is the same as the first alternative network but is further reduced by two sites: the industrial site Dry Branch Outfall and the commercial site White Rock Creek Outfall. Data collection for both these sites are complicated by hydraulic problems. The removal of these sites from the network is supported by the fact that the percentages of industrial and commercial land are small relative to the percentages of residential and undeveloped land. The remaining single-land-use sites are adequate to characterize the event mean concentrations from industrial and commercial land.

The third network alternative is summarized in table 11. This network is the same as the second alternative network except for the discontinuation of three more sites, the reactivation of one site, and establishment of two additional sites. The number and type of sites of this network more closely reflect the average distribution of land use in the seven cities. This network alternative consists of 5 residential, 2 commercial, 2 industrial, 2 highway, 6 mixed, and 2 undeveloped land use sites. Discontinuing the Pylon Street Outfall, Tributary to Duck Creek Outfall, and South Mesquite Creek Outfall at I-635 sites is proposed because those sites are less representative of their respective land-use categories than the other sites. The Tributary to Duck Creek Outfall site also is subject to backwater. The city of Garland site would be replaced with a discontinued, predominantly residential site from the 1992–94 sampling period (Sleepy Hollow Street Outfall). A new site, predominantly industrial, would be established in the city of Fort Worth and a new site, predominantly undeveloped, would be established in the city of Mesquite.

SUMMARY

About 450 stormwater samples were collected in the municipal stormwater network from February 1992–August 2000. The network comprises monitoring stations in the cities of Dallas, Fort Worth, Arlington, Garland,

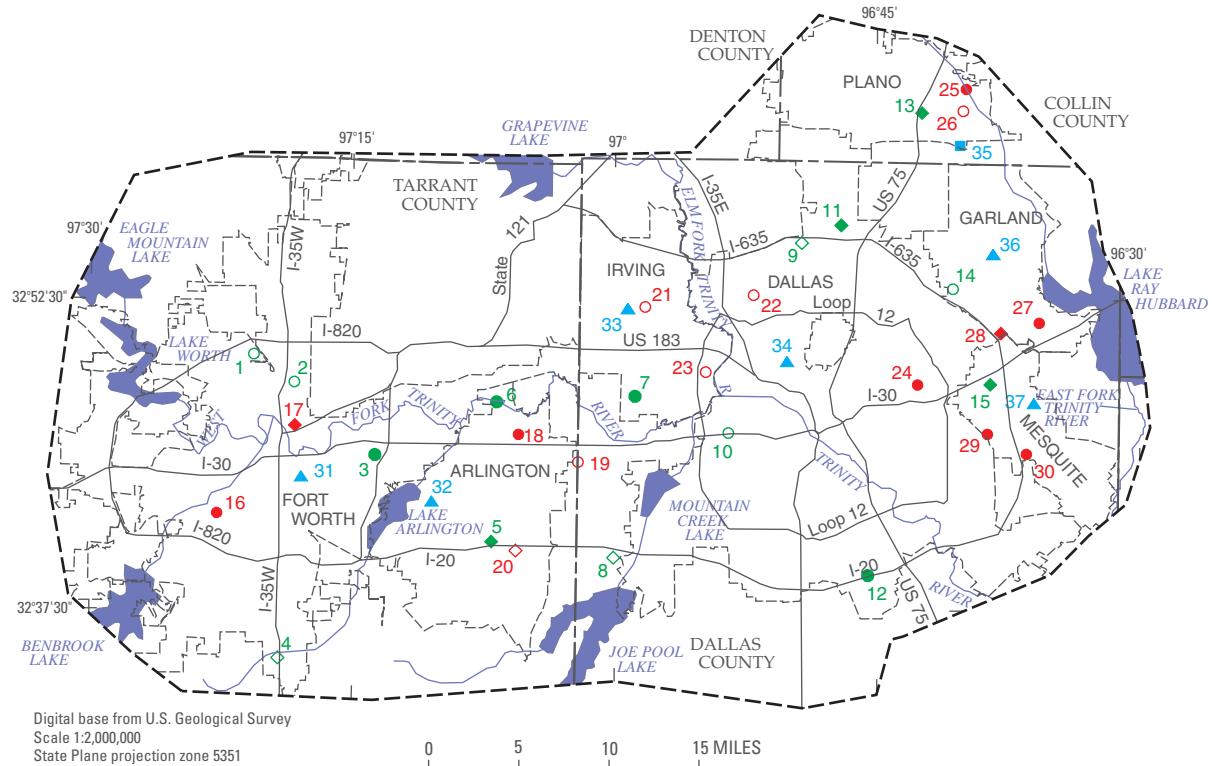

Irving, Plano, and Mequite, and the TxDOT Dallas and Fort Worth districts. Two-hundred ten samples were collected from a 30-site network of predominantly single-land-use sites during 1992–94. Each sample was analyzed for 188 properties and constituents. Two-hundred thirty eight samples were collected from a 22-site network during 1997–2000. Each sample was analyzed for 23 properties and constituents.

The 22-site network was evaluated on the basis of land-use, water-quality, hydraulic, and rainfall characteristics. The NCTCOG 1990 and 1995 land-use data were aggregated into seven categories. The cities typically are about 35-percent residential, 10-percent commercial, 5-percent industrial, 5-percent highway, 35-percent undeveloped, and 10-percent water and other. The 22-site network consists of 4 residential, 4 commercial, 4 industrial, 3 highway, 1 undeveloped, and 6 mixed land-use sites. Statistically significant differences in constituent concentrations between 1992–94 samples and 1997–2000 samples among all land uses were most common for diazinon and oil and grease. Four sites have backwater, one site has confined space and high-velocity-velocity conditions, and two sites have sediment build-up—all conditions that affect the accuracy and representativeness of sample collection. On the basis of the annual distribution of stormwater samples collected, storms during February–September are more frequent and more uniformly distributed than during March–August. Thus, scheduling more frequent sampling during February–September than during March–August is reasonable.

Three network alternatives were developed on the basis of the current (2000) network evaluation. All three alternatives propose collecting three samples per year at each current or reactivated site (two samples from September–February and one sample during March–August) and six samples per year at each new site (three samples from September–February and three sample during March–August). The first alternative consists of discontinuing two highway sites and adding one new highway site. The second alternative consists of discontinuing four sites (one industrial, one commercial, and two highway sites) and adding one new highway site. The third alternative consists of discontinuing seven sites (2 commercial, 3 industrial, and 2 highway sites), reactivating one residential site, and adding three sites (one highway, one industrial, and one undeveloped).

00400	pH, whole, field (standard units)	3	8,400	7,600	--	--	--	--	--	--
00095	Specific conductance ($\mu\text{S}/\text{cm}$ at 25 °C)	3	203,000	137,000	--	--	--	--	--	--
00010	Water temperature (degrees)	3	18,000	8,500	--	--	--	--	--	--
90410	Anc. tit. 4.5, L (mg/L as CaCO_3)	3	140,000	51,000	--	--	--	--	--	--
39036	Alkalinity, D, FE, (mg/L as CaCO_3)	3	52,000	21,000	--	--	--	--	--	--
00625	Nitrogen ammonia plus organic (mg/L as N)	3	3,100	.992	--	--	--	--	--	--
00631	NO_2 plus NO_3 dissolved (mg/L as N)	3	1,100	.224	--	--	--	--	--	--
00666	Phosphorus dissolved (mg/L as P)	3	.210	.040	--	--	--	--	--	--
00665	Phosphorus total (mg/L as P)	3	.480	.209	--	--	--	--	--	--
00310	BOD 5-day at 20 (mg/L)	3	8,800	3,300	--	--	--	--	--	--
00340	COD high level M (mg/L)	3	93,000	40,900	--	--	--	--	--	--
00530	Residue total (mg/L)	3	209,000	78,000	--	--	--	--	--	--
70300	Residue dissolved 180 °C (mg/L)	3	178,000	108,000	--	--	--	--	--	--

31625	Coliform fecal 0 (cols./100 ml)	3	95,000,000	14,000,000
31673	Fecal strpt KF A (cols./100 ml)	3	51,000,000	15,000,000
01002	Arsenic total ($\mu\text{g/L}$ as AS)	3	--	--
01027	Cadmium total ($\mu\text{g/L}$ as CD)	3	--	--
01034	Chromium total ($\mu\text{g/L}$ as CR)	3	15,000	4,600
01042	Copper total ($\mu\text{g/L}$ as CU)	3	28.700	14,400
01051	Lead total ($\mu\text{g/L}$ as PB)	3	30.000	20,000
01067	Nickel total ($\mu\text{g/L}$ as NI)	2	10,000	8,000
01092	Zinc total ($\mu\text{g/L}$ as ZN)	3	400,000	103,000
39570	Diazinon total (water $\mu\text{g/L}$)	2	--	--
00556	Oil and grease recoverable (mg/L)	3	69,000	2,000
32730	Phenols, total ($\mu\text{g/L}$)	3	--	--

¹Mean for pH not reported.

²Value is estimated by using a log-probability regression to predict the values of data below the detection limit.

Table 4. Statistical summary of $\text{NO}_2 + \text{NO}_3$ dissolved (mg/L as N) water-quality data collected during February 1992–August 2000
